Abstract

We give evidence that Single Transferable Vote (STV) is computationally resistant to manipulation: It is NP-complete to determine whether there exists a (possibly insincere) preference that will elect a favored candidate, even in an election for a single seat. Thus strategic voting under STV is qualitatively more difficult than under other commonly-used voting schemes. Furthermore, this resistance to manipulation is inherent to STV and does not depend on hopeful extraneous assumptions like the presumed difficulty of learning the preferences of the other voters.

We also prove that it is NP-complete to recognize when an STV election violates monotonicity. This suggests that non-monotonicity in STV elections might be perceived as less threatening since it is in effect “hidden” and hard to exploit for strategic advantage.

1 Strategic voting

For strategic voting the fundamental problem for any would-be manipulator is to decide what preference to claim. We will show that this modest task can be impractically difficult under the voting scheme known as Single Transferable Vote (STV). Furthermore this difficulty pertains even in the ideal situation in which the manipulator knows the preferences of all other voters and knows that they will vote their complete and sincere preferences. Thus STV is apparently unique among voting schemes in actual use today in that it is computationally resistant to manipulation. It might be that this resistance can help protect the integrity of social choice: If the work to construct a strategic preference is excessive, this might mean that strategic voting is not practical, even though theoretically possible.

Following the conventions of [11] we formalize the fundamental problem of strategic voting as the following “yes/no” question.

EFFECTIVE PREFERENCE

GIVEN: A set C of candidates; a distinguished candidate c ; and the set V of sincere, transitive, strict, and complete preferences of the voters.

QUESTION: Is there a preference ordering on C that when tallied with the preferences of V will ensure the election of c ?

A polynomial-time algorithm for **EFFECTIVE PREFERENCE** is one that will always answer the question correctly within a number of steps bounded above by a polynomial in the size of a description of the election (which is $O(|V||C|)$). Polynomial-time algorithms are considered fast because the work to answer the question does not increase too rapidly as a function of the size of the problem; similarly, problems for which there exist polynomial time algorithms are considered “easy”. In contrast, an algorithm which requires exponential time quickly becomes impractical as the size of the problem increases; accordingly, such problems are considered “hard”. This theoretical distinction is widely

borne out in practical experience [11].

The celebrated theorems of Gibbard, Satterthwaite, and Gärdenfors show that any voting scheme that is minimally fair is in principle susceptible to strategic voting; that is, there exist instances in which some voter has incentive to misrepresent his true preferences [10,12,21]. For a susceptible voting scheme, if there exists an algorithm that is guaranteed to answer EFFECTIVE PREFERENCE within polynomial time, then we say the voting scheme is *vulnerable*; otherwise the voting scheme is *resistant*.

This paper may be read as a companion to [3], which proved that most voting schemes in common use are vulnerable to strategic voting. Here we prove that STV, a voting scheme in practical use, is qualitatively different from the others in that it requires distinctly more effort to vote strategically. Thus STV might encourage sincere voting, since it can be difficult to do otherwise.

Results of this type were anticipated in [3], but until now it has not been possible to show a real voting scheme that is computationally resistant to manipulation. In [3] it was observed that voting schemes due to Dodgson and to Kemeny had the undesirable property that it is NP-hard to tell whether any particular candidate has won the election. Such schemes are hard to manipulate for the uninteresting reason that they are hard to operate. What is wanted is a voting scheme that supports quick computation for authorized use, such as determining winners, but erects computational barriers to abuse. In [3] there was displayed a scheme that computes winners quickly but resists manipulation. However it is a rather contrived scheme whose only use, as far as we know, has been as a tie-breaking rule by the International Federation of Chess. This paper, taken with the results of [3] suggest that STV is the only voting scheme in actual use that computes winners quickly (in polynomial time) but is inherently resistant to strategic voting.

Note that we are not arguing for the adoption of STV—it has troubling faults documented elsewhere [4,7,9,13,16]—rather we are suggesting that com-

putational properties ought to be among the criteria by which a prospective voting scheme is evaluated. In this regard STV differs in an interesting and possibly helpful way from other common voting schemes.

2 Single Transferable Vote

Under STV each voter submits a total order of the candidates. STV tallies votes by reallocating support from “weaker” candidates to “stronger” candidates and excess support from elected candidates to remaining contenders. In comparison with other voting schemes in practical use, it is rather complicated. However, despite its relative complexity, STV or its variants are used in elections for the parliaments of the Republic of Ireland, Tasmania, and Malta; for the senates of Northern Ireland, Australia, and South Africa; for all local authorities in the Republic of Ireland and some in Australia and Canada; and in the United Kingdom for many public and professional institutions, trade unions, and voluntary societies [17]. In the U. S. A. it is used by Cambridge, Massachusetts for the election of its city council and school committee and by New York City for the election of its district school boards [22]. John Stuart Mill praised its advantages as being “. . . such and so numerous . . . that, in my conviction, they place [STV] among the greatest improvements yet made in the theory and practice of government” [15]. Subsequent analysis has tempered this enthusiasm somewhat, since STV, like any voting system, must be imperfect. Most troubling of its weaknesses is that it is possible for a candidate to change from a winner to a loser as a result of gaining more support [7]. Nevertheless, STV has much to commend it, most notably its tendency to guarantee proportional representation. Largely for this property, STV is championed by such organizations as The Electoral Reform Society of Great Britain and Ireland [17].

We formalize STV as an algorithm in Figure 1, with supporting procedures in Figures 2, 3, and 4. All variants we know differ only in how they reallocate

excess support from an elected candidate to the remaining contenders. The “pure” form of STV uses the procedure given in Figure 4. For comparison, Figure 5 gives the procedure used by the city of Cambridge, Massachusetts. Our complexity results will hold for all such variants of STV, independently of how excess votes are reallocated.

For a picturesque rather than algorithmic description of STV, see [8]. For an official guide to one version of STV in practice, see *Rules for Counting Ballots under Proportional Representation*, City of Cambridge Election, 1941, reproduced in [22]. A good summary assessment of the strengths and weaknesses of STV may be found in [5].

3 Strategic voting under STV

Others have remarked on the apparent difficulty of strategic voting under an STV election. Most immediately, Steven J. Brams, in private communication to the first author, conjectured that strategic voting is computationally difficult under STV. In addition, Chamberlin found that by several empirical measures strategic voting under STV seemed more difficult than under other voting schemes he tested (Plurality, Borda, and Coombs) [6]. He observed that STV, in contrast to the other schemes, “. . . usually has a much more complex and election-specific manipulation strategy”. This is consistent with our results since the NP-completeness of EFFECTIVE PREFERENCE under STV means that there is no simple pattern, structure, or rule to simplify the construction of an effective preference. Thus, for each strategic voter, the search for an effective preference must be essentially enumerative search over an exponentially large set—even when the strategic voters are trying to coordinate their votes to achieve a common goal. In contrast, for Plurality, Borda, and Coombs it is always the case that a voter can, within polynomial time, either construct a strategic preference or else conclude that none exists [3].

```

procedure STV;
begin;
  InitializeScores();
  quota :=  $\lceil \frac{|V|}{k+1} + 1 \rceil$ ;
  repeat
    if any candidate has score  $\geq$  quota then
      status of candidate := elected;
      ReallocateVotesOfWinner( candidate );
    else
      with candidate of lowest score do
        status := defeated;
        ReallocateVotesOfLoser( candidate );
      end;
    end;
  until total of elected candidates and viable candidates =  $k$ ;
  for each remaining viable candidate do
    his status := Elected;
  end;
end;

```

Figure 1: STV, written in pseudo-Pascal. This tallies votes to elect k candidates from a set C based on the preferences of a set V of voters. A viable candidate is one who has not yet been defeated or elected.

```

procedure InitializeScores();
begin;
  for each candidate do
    his score := 1.0;
    his status := viable;
  end;
  for each ballot do
    its weight := 1.0;
    add its weight to the score of the first viable candidate on ballot;
  end;
end;

```

Figure 2: Procedure to initialize scores for the STV algorithm

```

procedure ReallocateVotesOfLoser( candidate );
begin;
  for each ballot do
    if candidate is the first viable candidate on the ballot then
      Increase score of next viable candidate on ballot by weight of ballot;
    end;
  end;
end;

```

Figure 3: Procedure ReallocateVotesOfLoser

```

procedure ReallocateVotesOfWinner( candidate );
begin;
  excess votes for candidate := score of candidate - quota;
  for each ballot do
    if candidate is the first viable candidate on the ballot then
      Set weight of this ballot := (weight) (excess/score);
      Increase score of next viable candidate on ballot by weight of ballot;
    end;
  end;
end;

```

Figure 4: Procedure ReallocateVotesOfWinner for the “pure” form of STV

```

procedure ReallocateVotesOfWinner( candidate );
begin;
  excess votes for candidate := score of candidate - quota;
  for j := 1 to excess do
    Draw a ballot randomly from among those on which candidate is the
      first viable candidate;
    Increase score of next viable candidate on ballot by weight of ballot;
  end;
end;

```

Figure 5: Procedure ReallocateVotesOfWinner for the variant of STV that is used in Cambridge, Massachusetts

We will prove that EFFECTIVE PREFERENCE is hard, even for the special case of STV in which all candidate vie for a single seat. In this case the voting scheme works by successively eliminating a candidate with the fewest votes and reallocating his support. This type of voting scheme is also called *alternative voting* or *successive elimination*. The following is strong theoretical evidence that there is no dependably fast algorithm to solve EFFECTIVE PREFERENCE under Successive Elimination.

Theorem 1 *EFFECTIVE PREFERENCE is NP-complete under Successive Elimination.*

Proof First observe that EFFECTIVE PREFERENCE under Successive Elimination is in NP, since the effectiveness of a preference can be verified in polynomial time by tallying the election and checking whether c wins.

Now we prove that EFFECTIVE PREFERENCE under Successive Elimination is “as hard as” the following problem that is known to be NP-complete [11].

3-COVER

GIVEN: A set S with $|S| = n$; subsets $S_1, \dots, S_m \subset S$, with $|S_i| = 3$ for $i = 1, \dots, m$.

QUESTION: Does there exist an index set I with $|I| = n/3$ and $\bigcup_{i \in I} S_i = S$?

Now let $\{S_1, \dots, S_m\}$ denote an instance of 3-COVER. We will create an STV election for which there exists an effective preference if and only if there exists a 3-cover for S . Our contrived election will be to select a single winner from among $5m + n + 3$ candidates. In this election the candidates fall naturally into the following five groups.

1. “possible winners” c and w ;
2. “first losers” a_1, \dots, a_m and $\bar{a}_1, \dots, \bar{a}_m$;
3. “second line” b_1, \dots, b_m and $\bar{b}_1, \dots, \bar{b}_m$;

4. “w-bloc” d_0, d_1, \dots, d_n ;
5. “garbage collectors” g_1, \dots, g_m ;

The election we construct will have the following properties.

Property 1: Of the first $3m$ candidates to be eliminated, $2m$ of them are a_1, \dots, a_m and $\bar{a}_1, \dots, \bar{a}_m$.

Property 2: Let $I = \{i : \bar{a}_i \text{ is eliminated prior to } a_i\}$. Then c will win the election if and only if I is a 3-cover.

Property 3: For any specified index set $I \subseteq \{1, \dots, m\}$, there exists a preference which, when tallied with all the other preferences, guarantees that \bar{a}_i is eliminated prior to a_i if and only if $i \in I$. Furthermore, such a preference can be constructed by allocating the first m positions on the preference list as follows: if $i \in I$ then place a_i in the i th position; otherwise place \bar{a}_i in the i th position.

Properties 1–3 together imply that a strategic voter can guarantee victory for c in this election if and only if he can solve the 3-cover problem.

Now we describe the details of our contrived election. The voters are as follows. (Wherever we leave preferences unspecified, they can be arbitrary.)

- $12m$ voters with preference (c, \dots) ;
- $12m - 1$ voters with preference (w, c, \dots) ;
- $10m + (2n/3)$ voters with preference (d_0, w, c, \dots) ;
- For each $i = 1, \dots, n$, $12m - 2$ voters with preference (d_i, w, c, \dots) ;
- For each $i = 1, \dots, m$, $12m$ voters with preference (g_i, w, c, \dots) ;
- For each $i = 1, \dots, m$: $6m + 4i - 5$ voters with preference $(b_i, \bar{b}_i, w, c, \dots)$ and, for each of the three j such that $j \in S_i$, 2 voters with preference (b_i, d_j, w, c, \dots) ;
- For each $i = 1, \dots, m$: $6m + 4i - 1$ voters with preference $(\bar{b}_i, b_i, w, c, \dots)$ and 2 voters with preference $(\bar{b}_i, d_0, w, c, \dots)$;

- For each $i = 1, \dots, m$: $6m + 4i - 3$ voters with preference (a_i, g_i, w, c, \dots) ; 1 voter with preference (a_i, b_i, w, c, \dots) ; and 2 voters with preferences $(a_i, \bar{a}_i, w, c, \dots)$;
- For each $i = 1, \dots, m$: $6m + 4i - 3$ voters with preference $(\bar{a}_i, g_i, w, c, \dots)$; 1 voter with preference $(\bar{a}_i, \bar{b}_i, w, c, \dots)$; and 2 voters with preferences $(\bar{a}_i, a_i, w, c, \dots)$;

Now we consider the election.

Votes for c and w. Initially c has $12m$ votes and w has $12m - 1$ votes. Except for the $12m$ initial supporters of c , all voters rank c immediately below w . Thus c cannot get another vote until w is eliminated. Moreover, if w gets another 2 votes, then w cannot be eliminated before c . Thus, to be effective, a strategic preference must ensure that w is eliminated from the election before c .

The w-bloc. Candidate d_0 initially receives $10m + 2n/3$ votes and each of the other d_i receives $12m - 2$ votes. For every voter whose first choice is d_i , the second choice is w , so that if any d_i is eliminated prior to w , then w will obtain more than 2 additional votes, and c cannot win. Thus the strategic voter must ensure that each candidate d_i achieves a score of at least $12m$. We will contrive the remainder of the election so that this can be accomplished only if certain of the “second line” candidates are eliminated early and their votes reallocated to candidates in the w -bloc.

The second line. Candidate b_i initially receives $6m + 4i + 1$ votes. If b_i is eliminated, his votes are reallocated as follows: for each $j \in S_i$, 2 votes go to d_j and the remainder go to \bar{b}_i . Similarly, candidate \bar{b}_i also receives $6m + 4i + 1$ votes initially. If \bar{b}_i is eliminated, his votes are reallocated as follows: 2 votes go to d_0 and the remainder go to b_i . The third choice of all initial supporters of b_i or \bar{b}_i is w .

Note that if b_i is eliminated before \bar{b}_i , then the revised score of \bar{b}_i will exceed $12m$. Similarly, if \bar{b}_i is eliminated before b_i , then the revised score of b_i will

exceed $12\bar{m}$. This means that at most one of b_i, \bar{b}_i can be eliminated before c or w .

The First Losers. The initial score of each candidate a_i, \bar{a}_i is $6m + 4i$, which is one less than b_i and \bar{b}_i . If a_i is eliminated, his votes are reallocated as follows: 1 vote goes to b_i ; 2 votes go to \bar{a}_i ; and the remainder goes to g_i . Similarly, if \bar{a}_i is eliminated, his votes are reallocated as follows: 1 vote goes to \bar{b}_i ; 2 votes go to a_i ; and the remainder goes to g_i .

The Garbage Collectors. Each candidate g_i initially has $12m$ votes.

Now we show how the sequence in which candidates are eliminated in the election can encode a 3-cover.

Lemma 1 *Exactly one of b_i, \bar{b}_i will be among the first $3m$ candidates to be eliminated. Furthermore, candidate c will win the election if and only if the set $J = \{j : b_j \text{ is among the first } 3m \text{ candidates to be eliminated}\}$ is the index of a set cover for the 3-cover problem.*

Proof The first claim is true because the first $3m$ candidates to be eliminated must be among the $a_i, \bar{a}_i, b_i, \bar{b}_i$; and if one of b_i, \bar{b}_i is eliminated, then the other will have score exceeding $12m$.

To establish the second claim, suppose that J is the index of a set cover. Then $|J| = n/3$. Consider the election after the first $3m$ candidates have been eliminated. Suppose $i \in S_j$ and $j \in J$. Then b_j has been eliminated and a_i has received 2 of b_j 's votes. Thus the revised score of d_i is at least $12m$, which exceeds that of w . Since J is the index of a set cover, each $d_i, i = 1, \dots, m$, has a revised score of at least $12m$. Also, \bar{b}_j has been eliminated for $j \notin J$. Thus $m - n/3$ of the b_j 's have been eliminated and the revised score of d_0 is at least $(10m + 2n/3) + 2(m - n/3) = 12m$, which exceeds that of candidate w .

After $3m$ candidates have been eliminated there remain only c, w , all the d_i , all the g_i, b_j for $j \notin J, \bar{b}_j$ for $j \in J$, all of which excepting w have at least $12m$

votes. Candidate w , with $12m - 1$ votes, will be eliminated next. Candidate c will inherit his votes and his score will rise to at least $24m - 1$.

Next the d_i candidates are eliminated since each has only $12m$ votes. The votes of each d_i are reallocated to c , whose score rises to at least $(24m - 1) + (n + 1)(12m) = (12n + 36)m - 1$.

Now no g_i has more than then $24m + 8m = 32m$ votes. Similarly, no remaining b_i or \bar{b}_i has more than $32m$ votes. Since each g_i , b_i , or \bar{b}_i that is eliminated will have his votes reallocated to c , it must be that c is the eventual winner of the election.

Conversely, suppose that J is not the index of a set cover; we will show that c cannot win the election. If $|J| > n/3$, then fewer than $m - n/3$ of the \bar{b}_j 's have been eliminated, and the revised score of d_0 cannot exceed $12m - 2$. Thus d_0 will be eliminated prior to w , and w will receive his votes and achieve a higher score than c . In such case w cannot be eliminated before c and so c cannot win the election.

If $|J| \leq n/3$ and $i \in S$ is not covered by the corresponding set cover, then the score of d_i has not increased and d_i must be eliminated before w . Thus w will receive his votes and achieve a higher score than c . Again w cannot be eliminated before c and so c cannot win the election. \square

Now we show how to construct a preference that will control which of the b_i are among the first $3m$ candidates to be eliminated.

Lemma 2 *Let $I \subseteq \{1, \dots, m\}$ and consider the strategic preference in which the i th candidate is a_i if $i \in I$ and \bar{a}_i otherwise. Then the following is the order in which the first $3m$ candidates are eliminated.*

- The $3i - 2$ candidate to be eliminated is \bar{a}_i if $i \in I$, and a_i otherwise;
- The $3i - 1$ candidate to be eliminated is b_i if $i \in I$, and \bar{b}_i otherwise;
- The $3i$ candidate to be eliminated is a_i if $i \in I$, and \bar{a}_i otherwise;

Proof (By induction) Assume that the first $3i - 3$ candidates have been eliminated and that these candidates were, for each $j < i$, both a_j and \bar{a}_j and exactly one of each pair b_j, \bar{b}_j .

Case 1 $i \in I$. The next viable candidate on the strategic preference is a_i , who therefore has $6m + 4i + 1$ votes. Candidate \bar{a}_i has $6m + 4i$ votes and is eliminated, after which the revised score of b_i is $6m + 4i + 1$; the revised score of \bar{b}_i is $6m + 4i + 2$; and the revised score of a_i is $6m + 4i + 3$. Next, candidate b_i is eliminated, followed by a_i . Thus, by induction, the elimination of candidates is as claimed.

Case 2 $i \notin I$. The next viable candidate on the strategic preference is \bar{a}_i . Candidate a_i must be eliminated next, after which the revised score of \bar{b}_i is $6m + 4i + 1$; the revised score of b_i is $6m + 4i + 2$; and the revised score of \bar{a}_i is $6m + 4i + 3$. Next, candidate \bar{b}_i is eliminated, followed by \bar{a}_i . By induction, the elimination of candidates is as stated in the theorem.

□

Now by Lemmas 1 and 2 candidate c will win the election if and only if I is a solution to the set cover problem. □

Now since the single elimination voting scheme is a special case of STV in all its variants, we have our main result.

Corollary 1 *EFFECTIVE PREFERENCE under STV is NP-hard independently of how the excess votes of a winning candidate are reallocated among the remaining contenders.*

4 Non-monotonicity

A voting procedure is *monotonic* if it does not respond negatively to changes in the preferences of voters; that is, a candidate can never be hurt if some

voters move him up in their preferences. Doron and Kronick have shown that STV is non-monotonic: there exist elections for which a candidate can change from an STV winner to a loser simply as a result of gaining support [7]. We show that it is NP-complete to recognize when non-monotonicity occurs in STV elections. Thus it can be impractical to exploit non-monotonicity for strategic purposes. To some extent this weakens any argument against STV that is based on non-monotonicity. Since non-monotonicity can be hard to recognize, voters are unlikely to be regaled with examples of its pernicious effects in real elections. Furthermore, even if voters know that non-monotonicity is possible, its distortions, since hidden, might be perceived as “random” and even, since unlikely to be exploited, benign. It might be seen by voters as similar in spirit to the randomness occasionally designed into voting systems, as in [22]. Thus non-monotonicity might be more easily tolerated than flaws that are easy to find. When flaws are easy to find, then they are more likely to be exploited by manipulators and they are easier to display to an outraged electorate. Indeed, when flaws easy to find, manipulative behavior might be encouraged, while if flaws are hard to find, manipulative behavior might be uneconomic.

Doron and Kronick argue that any non-monotonic voting procedure is “perverse”. They vividly make their point by imagining an STV election in which it is observed that non-monotonicity affected the outcome.

Most voters would probably be alienated and outraged upon hearing the hypothetical (but theoretically possible) election night report: “Mr. O’Grady did not obtain a seat in today’s election, but if 5,000 of his supporters had voted for him in second place instead of first place, he would have won!”

However, because it is NP-complete to recognize an instance of non-monotonicity, voters would almost certainly *not* hear any such news on election night. In fact they would probably would never hear it—not because the claim was false, but because it would simply take too long to discover.

We formalize the problem of recognizing non-monotonicity as follows.

NON-MONOTONICITY

GIVEN: A set C of candidates; the set V of sincere, transitive, strict, and complete preferences of the voters; and a distinguished candidate $c \in C$ who would be a loser if the election was tallied now.

QUESTION: Is there a subset of voters in V who can change c from a loser to a winner by lowering c in their preferences?

Theorem 2 *NON-MONOTONICITY is NP-complete for Successive Elimination.*

Proof Our proof is similar to that of Theorem 1 and so we omit details. Again let $\{S_1, \dots, S_m\}$ denote an instance of 3-COVER. Consider the following election (which is almost the same as in the proof to Theorem 1).

- $12m$ voters with preference (c, w, \dots) ;
- $12m - 1$ voters with preference (w, c, \dots) ;
- $12m$ voters with preference (w', w, c, \dots) ;
- $10m + (2n/3)$ voters with preference (d_0, w, c, \dots) ;
- For each $i = 1, \dots, n$, $12m - 2$ voters with preference (d_i, w, c, \dots) ;
- For each $i = 1, \dots, m$, $12m$ voters with preference (g_i, w, c, \dots) ;
- For each $i = 1, \dots, m$: $6m$ voters with preference $(b_i, \bar{b}_i, w, c, \dots)$ and, for each of the three j such that $j \in S_i$, 2 voters with preference (b_i, d_j, w, c, \dots) ;
- For each $i = 1, \dots, m$: $6m$ voters with preference $(\bar{b}_i, b_i, w, c, \dots)$ and 2 voters with preference $(\bar{b}_i, d_0, w, c, \dots)$;
- For each $i = 1, \dots, m$: 1 voter with preference (c, b_i, \dots) and 1 voter with preference (c, \bar{b}_i, \dots) ;

Candidate c will lose this election since reallocated votes will always go to w before c . However the last group of voters, and only that group, can make

c a winner by moving him down on their preferences. By lowering c in the appropriate preferences of the last group of voters, w can be prevented from gaining any (reallocated) votes until all remaining candidates have at least $12m$ votes; then w will be eliminated and c will win the election. The preferences in which c must be moved down are exactly those (c, b_i, \dots) and (c, \bar{b}_i, \dots) for which the $\{i\} \subseteq \{1, \dots, m\}$ is a solution to the 3-cover problem. \square

Corollary 2 *NON-MONOTONICITY under STV is NP-hard independently of how the excess votes of a winning candidate are reallocated among the remaining contenders.*

Finally, we slightly strengthen the example of [7] by observing even a single voter in an STV election can change a candidate from winner to loser by moving him up in his preferences: In the contrived election of Theorem 1, if the manipulative voter constructs an effective preference then his favored candidate c will win; but if the voter moves c to the top of his preferences then c will lose. Thus STV is apparently as sensitive as it can be to changes in preferences; that is, non-monotonicity can be realized by even a single voter.

5 Conclusions

There are several ways to measure the vulnerability of a voting procedure to strategic voting (see, for example, [6,18,20]). We have suggested measuring the computational effort. This complements the established approach, which is to count the opportunities for manipulation. Both of these measures of manipulability are useful but imperfect. The primary weakness of the former is that it is a worst-case measure. A weakness of the latter is that it is based on some assumption about the distribution of societies and that assumption is difficult to justify. Frequently it is chosen for convenience of analysis.

We think that even the weakest reading of our theorem makes three contributions. First, we have explained Chamberlin’s empirical observation that strategies to manipulate STV are complex and instance-specific [6]. Also, our results show how a would-be manipulator is constrained to plot his strategy in an STV election: he cannot do significantly better than enumerative search for an effective preference. This is different from other standard voting procedures, for which a natural, “greedy” algorithm will either produce an effective preference or show that none exists [3]. Finally, our result refines the conclusions of impossibility theorems such as those of Gibbard, Satterthwaite, and Gärdenfors: All voting procedures have flaws, but for some it can be difficult to exploit those flaws.

The strongest interpretation of our result is that one cannot in practice expect to vote strategically in an STV election, even given perfect information. This probably overstates the case, for like some of the notions of fairness, computational complexity does not perfectly model our concerns. In particular, the caveats of [3] hold here, the most important of which we briefly summarize. Most immediately, NP-completeness is an asymptotic, worst-case measure of complexity. This means that, for large enough instances of EFFECTIVE PREFERENCE under STV, *some* are difficult. This might be insufficient to provide practical protection against strategic voting. Certainly for small enough elections one can simply generate each of the $|C|!$ possible preference orders and check each one to see whether it elects the favored candidate. Whether elections with many candidates are in fact difficult to manipulate is an empirical question. Naturally this will depend on the structure of a “typical” instance. It is worth remarking that Chamberlin’s observations on the complexity of manipulating STV were based on small elections (3 candidates and electorates of size 21 and 1000); this suggests that the computational difficulty becomes palpable rather quickly as the size of the election increases.

We close with some additional comments on points that are frequently mis-

understood. First, it is important to note that our assumptions of perfect information and sincere voting by most of the voters are *intentionally* unrealistic—we are not describing voter behavior, but making a conservative assumption to show that even when the situation is unrealistically favorable it can still be too difficult to determine how to vote strategically. Furthermore, we have shown that it is difficult for even a single manipulator to determine how to vote. One expects it to be only harder, at least in an informal sense, for a group of people to coordinate their votes to achieve a preferred outcome.

A second possible misunderstanding is that one might be tempted to conclude, by the contrived nature of the election in the proof of Theorem 1, that only pathological instances are difficult. This would be overinterpreting the proof. The contrived nature of our election is an artifact of human proof-building: We needed only to show that there exist some instances that are as difficult as another hard problem; we constructed an instance that made our proof as simple as possible, but not necessarily representative. In short, our theorem does not say whether any particular election is difficult to manipulate.

We also point out that the issues of computational difficulty are only intensified when the computational device is a relatively slow one, such as a person with pencil and paper. For example, in [14] it was reported that the site of the 1996 Summer Olympics was chosen by successive elimination, with six cities voted on by the 88 members of the International Olympic Committee. Our results imply that, even with perfect information, a strategic voter would have had to perform enumerative search for an effective preference over $6! = 840$ possibilities. Even if 90% of the possible preferences could have been eliminated *a priori*, the prospect of evaluating the remaining 84 elections by hand might have been sufficiently discouraging to prevent strategic voting.

Finally, we speculate on some broader suggestions of our results. For STV elections we have established the formal difficulty of recognizing when strategic voting is possible and of recognizing instances of non-monotonicity. Most imme-

diately, this suggests that STV might rise somewhat in our estimation, since two of its weaknesses—susceptibility to strategic voting and non-monotonicity—are perhaps less threatening than previously thought.

More generally, we have illustrated that even when voting procedures can fail to satisfy fairness criteria, nevertheless it can be hard to verify when this occurs. This might be interpreted as offering an explanation for an observation made by Nurmi and others of the “...the differences in difficulty of devising counterexamples showing the violations of criteria by various procedures. For some procedures and criteria the productions of a counterexample may be rather obvious while for other procedures it may be exceedingly difficult” [19].
